<sup>2</sup> Dept. of Math. Hiroshima University [m-mat@math.sci.hiroshima-u.ac.jp](mailto:m-mat@math.sci.hiroshima-u.ac.jp)

**Summary.** Mersenne Twister (MT) is a widely-used fast pseudorandom number generator (PRNG) with a long period of  $2^{19937} - 1$ , designed 10 years ago based on 32-bit operations. In this decade, CPUs for personal computers have acquired new features, such as Single Instruction Multiple Data (SIMD) operations (i.e., 128-bit operations) and multi-stage pipelines. Here we propose a 128-bit based PRNG, named SIMD-oriented Fast Mersenne Twister (SFMT), which is analogous to MT but making full use of these features. Its recursion fits pipeline processing better than MT, and it is roughly twice as fast as optimised MT using SIMD operations. Moreover, the dimension of equidistribution of SFMT, as a 32-bit integer generator, is better than MT.

We also introduce a block-generation function, which fills an array of 32-bit integers at one time. It speeds up the generation by a factor of two. A speed comparison with other modern generators, such as multiplicative recursive generators, shows an advantage of SFMT.

## 1 Introduction

Recently, the scale of simulations is getting larger, and faster pseudorandom number generators (PRNGs) are required. The power of CPUs for usual personal computers are now sufficiently strong for such purposes, and the necessity of efficient PRNGs for CPUs on PCs is increasing. One such generator is Mersenne Twister (MT) [8], which is based on a linear recursion modulo 2 over 32-bit words. An implementation MT19937 has the period of  $2^{19937} - 1$ .

MT was designed 10 years ago, and the architectures of CPUs for Personal Computers, such as Pentium and PowerPC, have changed. They have Single Instruction Multiple Data (SIMD) operations, which may be regarded as operations on 128-bit registers. Also, they have more registers and automatic parallelisms by multi-stage pipelining. These are not reflected in the design of MT.

In this article, we propose an MT-like pseudorandom number generator that makes full use of these new features: SFMT, SIMD-oriented Mersenne Twister. We implemented an SFMT with the period a multiple of  $2^{19937} - 1$ , named SFMT19937, which has a better equidistribution property than MT. SFMT is much faster than MT, even without using SIMD instructions.

There is an argument that the CPU time consumed for function calls to PRNG routines occupies a large part of the random number generation, and consequently it is not so important to improve the speed of PRNG (cf. [11]). This is not always the case: one can avoid the function calls by (1) inline-expansion and/or (2) generation of pseudorandom numbers in an array at one call. Actually some demanding users re-coded MT to avoid the function call; see the homepage of [8]. In this article, we introduce a block-generation scheme which is much faster than using function calls.

## 2 SIMD-oriented Fast Mersenne Twister

We propose SIMD-oriented Fast Mersenne Twister (SFMT) pseudorandom number generator. It is a Linear Feedbacked Shift Register (LFSR) generator based on a recursion over  $\mathbb{F}_2^{128}$ . We identify the set of bit  $\{0, 1\}$  with the two element field  $\mathbb{F}_2$ . This means that every arithmetic operation is done modulo 2. A  $w$ -bit integer is identified with a horizontal vector in  $\mathbb{F}_2^w$ , and  $+$  denotes the sum as vectors (i.e., bit-wise exor), not as integers. We consider three cases:  $w$  is 32, 64 or 128.

### 2.1 LFSR generators

A LFSR method is to generate a sequence  $\mathbf{x}_0, \mathbf{x}_1, \mathbf{x}_2, \dots$  of elements  $\mathbb{F}_2^w$  by a recursion

$$\mathbf{x}_{i+N} := g(\mathbf{x}_i, \mathbf{x}_{i+1}, \dots, \mathbf{x}_{i+N-1}), \quad (1)$$

where  $\mathbf{x}_i \in \mathbb{F}_2^w$  and  $g : (\mathbb{F}_2^w)^N \rightarrow \mathbb{F}_2^w$  is an  $\mathbb{F}_2$ -linear function (i.e., the multiplication of a  $(wN \times w)$ -matrix from the right to a  $wN$ -dimensional vector) and use it as a pseudorandom  $w$ -bit integer sequence. In the implementation, this recursion is computed by using an array  $\mathbf{W}[0..N-1]$  of  $N$  integers of  $w$ -bit size, by the simultaneous substitutions

$$\mathbf{W}[0] \leftarrow \mathbf{W}[1], \mathbf{W}[1] \leftarrow \mathbf{W}[2], \dots, \mathbf{W}[N-2] \leftarrow \mathbf{W}[N-1], \mathbf{W}[N-1] \leftarrow g(\mathbf{W}[0], \dots, \mathbf{W}[N-1]).$$

The first  $N - 1$  substitutions shift the content of the array, hence the name of LFSR. Note that in the implementation we may use an indexing technique to avoid computing these substitutions, see [5, P.28 Algorithm A]. The array  $\mathbf{W}[0..N-1]$  is called the state array. Before starting the generation, we need to set some values to the state array, which is called the initialization.

Mersenne Twister (MT) [8] is an example with

$$g(\mathbf{w}_0, \dots, \mathbf{w}_{N-1}) = (\mathbf{w}_0 | \mathbf{w}_1)A + \mathbf{w}_M,$$

where  $(\mathbf{w}_0 | \mathbf{w}_1)$  denotes the concatenation of  $32 - r$  MSBs of  $\mathbf{w}_0$  and  $r$  LSBs of  $\mathbf{w}_1$ , and  $A$  is a  $(32 \times 32)$ -matrix for which the multiplication  $\mathbf{w}A$  is computable by a few bit-operations, and  $M$  is an integer ( $1 < M < N$ ). Its period is  $2^{32N-r} - 1$ , chosen to be a Mersenne prime. To obtain a better equidistribution property, MT transforms the sequence by a suitably chosen  $(32 \times 32)$  matrix  $T$ , namely, MT outputs  $\mathbf{x}_0T, \mathbf{x}_1T, \mathbf{x}_2T, \dots$  (called tempering).

## 2.2 New features of modern CPUs for personal computers

Modern CPUs for personal computers (e.g. Pentium and PowerPC) have new features such as (1) fast integer multiplication instructions (2) fast floating point operations (3) SIMD operations (4) multi-stage pipelining. These were not common to standard PC CPUs, when MT was designed.

An advantage of  $\mathbb{F}_2$ -linear generators over integer multiplication generators (such as Linear Congruential Generators [5] or Multiple Recursive Generators [6]) was high-speed generation by avoiding multiplications. This advantage is now smaller, since 32-bit integer multiplication is now quite fast.

Among the new features, (3) and (4) fit  $\mathbb{F}_2$ -linear generators. Our idea is simple: to design a 128-bit integer PRNG, considering the benefit of such parallelism in the recursion.

## 2.3 The recursion of SFMT

We choose  $g$  in the recursion (1) as

$$g(\mathbf{w}_0, \dots, \mathbf{w}_{N-1}) = \mathbf{w}_0A + \mathbf{w}_MB + \mathbf{w}_{N-2}C + \mathbf{w}_{N-1}D, \quad (2)$$

where  $\mathbf{w}_0, \mathbf{w}_M, \dots$  are  $w(=128)$ -bit integers (= horizontal vectors in  $\mathbb{F}_2^{128}$ ), and  $A, B, C, D$  are sparse  $128 \times 128$  matrices over  $\mathbb{F}_2$  for which  $\mathbf{w}A, \mathbf{w}B, \mathbf{w}C, \mathbf{w}D$  can be computed by a few SIMD bit-operations. The choice of the suffixes  $N-1, N-2$  is for speed: in the implementation of  $g$ ,  $\mathbf{w}[0]$  and  $\mathbf{w}[M]$  are read from the array  $\mathbf{w}$ , while the copies of  $\mathbf{w}[N-2]$  and  $\mathbf{w}[N-1]$  are kept in two 128-bit registers in the CPU, say  $\mathbf{r1}$  and  $\mathbf{r2}$ . Concretely speaking, we assign  $\mathbf{r2} \leftarrow \mathbf{r1}$  and  $\mathbf{r1} \leftarrow$  “the result of (2)” at every generation, then  $\mathbf{r2}$  ( $\mathbf{r1}$ ) keeps a copy of  $\mathbf{w}[N-2]$  ( $\mathbf{w}[N-1]$ , respectively). The merit of doing this is to use the pipeline effectively. To fetch  $\mathbf{w}[0]$  and  $\mathbf{w}[M]$  from memory takes some time. In the meantime, the CPU can compute  $\mathbf{w}_{N-2}C$  and  $\mathbf{w}_{N-1}D$ , because copies of  $\mathbf{w}_{N-2}$  and  $\mathbf{w}_{N-1}$  are kept in the registers. This selection was made through experiments on the speed of generation.

By trial and error, we searched for a set of parameters of SFMT, with the period being a multiple of  $2^{19937} - 1$  and having good equidistribution properties. The degree of recursion  $N$  is  $\lceil 19937/128 \rceil = 156$ , and the linear transformations  $A, B, C, D$  are as follows.

- $\mathbf{w}A := (\mathbf{w} \overset{128}{\ll} 8) + \mathbf{w}$ .  
This notation means that  $\mathbf{w}$  is regarded as a single 128-bit integer, and  $\mathbf{w}A$  is the result of the left-shift of  $\mathbf{w}$  by 8 bits. There is such a SIMD operation in both Pentium SSE2 and PowerPC AltiVec SIMD instruction sets (SSE2 permits only a multiple of 8 as the amount of shifting). Note that the notation  $+$  means the exclusive-or in this article.
- $\mathbf{w}B := (\mathbf{w} \overset{32}{\gg} 11) \& (\text{BFFFFFF6 BFFAFFFF DDFECB7F DFFFFFFEF})$ .  
This notation means that  $\mathbf{w}$  is considered to be a quadruple of 32-bit integers, and each 32-bit integer is shifted to the right by 11 bits, (thus the eleven most significant bits are filled with 0s, for each 32-bit integer). The C-like notation  $\&$  means the bitwise AND with a constant 128-bit integer, denoted in the hexadecimal form.  
In the search, this constant is randomly generated as follows. Each bit in the 128-bit integer is independently randomly chosen, with the probability to choose 1 being  $7/8$ . This is because we prefer to have more 1's for a denser feedback.
- $\mathbf{w}C := (\mathbf{w} \overset{128}{\gg} 8)$ .  
The notation  $(\mathbf{w} \overset{128}{\gg} 8)$  is the right shift of an 128-bit integer by 8 bits, similar to the first.
- $\mathbf{w}D := (\mathbf{w} \overset{32}{\ll} 18)$ .  
Similar to the second,  $\mathbf{w}$  is cut into four pieces of 32-bit integers, and each of these is shifted by 18 bits to the left.

All these instructions are available in both Intel Pentium's SSE2 and PowerPC's AltiVec SIMD instruction sets. Figure 1 shows a concrete description of SFMT19937 generator with period a multiple of  $2^{19937} - 1$ .

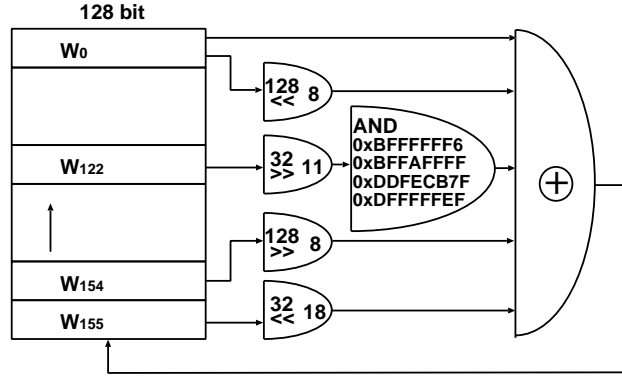

Fig. 1. A circuit-like description of SFMT19937.

### 3 How to select the recursion and parameters.

We wrote a code to compute the period and the dimensions of equidistribution (DE, see §3.2). Then, we search for a recursion with good DE admitting a fast implementation.

#### 3.1 Computation of the Period

LFSR by the recursion (1) may be considered as an automaton, with the state space  $S = (\mathbb{F}_2^w)^N$  and the state transition function  $f : S \rightarrow S$  given by  $(\mathbf{w}_0, \dots, \mathbf{w}_{N-1}) \mapsto (\mathbf{w}_1, \dots, \mathbf{w}_{N-1}, g(\mathbf{w}_0, \dots, \mathbf{w}_{N-1}))$ . As a  $w$ -bit integer generator, the output function is  $o : S \rightarrow \mathbb{F}_2^w$ ,  $(\mathbf{w}_0, \dots, \mathbf{w}_{N-1}) \mapsto \mathbf{w}_0$ .

Let  $\chi_f$  be the characteristic polynomial of  $f : S \rightarrow S$ . If  $\chi_f$  is primitive, then the period of the state transition takes the maximal value  $2^{\dim(S)} - 1$  [5, §3.2.2]. However, to check the primitivity, we need the integer factorization of this number, which is often hard for  $\dim(S) = nw > 10000$ . On the other hand, the primality test is much easier than the factorization, so many huge primes of the form  $2^p - 1$  have been found. Such a prime is called a Mersenne prime, and  $p$  is called the Mersenne exponent, which itself is a prime.

MT and WELL[12] discard some fixed  $r$ -bits from the array  $S$ , so that  $nw - r$  is a Mersenne exponent. Then, the primitivity of  $\chi_f$  is easily checked by the algorithm in [5, §3.2.2], avoiding the integer factorization.

SFMT adopted another method to avoid the integer factorization, the reducible transition method (RTM), which uses a reducible characteristic polynomial. This idea appeared in [4] [1][2], and applications in the present context are discussed in detail in another article [13], therefore we only briefly recall it.

Let  $p$  be the Mersenne exponent, and  $N := \lceil p/w \rceil$ . Then, we randomly choose parameters for the recursion of LFSR (1). By applying the Berlekamp-Massey Algorithm to the output sequence, we obtain the minimal polynomial of the transition function  $f$ . (Note that a direct computation of  $\det(tI - f)$  is time-consuming because  $\dim(S) = 19968$ .)

By using a sieve, we remove all factors of small degree from  $\chi_f$ , until we know that it has no irreducible factor of degree  $p$ , or that it has a (possibly reducible) factor of degree  $p$ . In the latter case, the factor is passed to the primitivity test described in [5, §3.2.2].

Suppose that we found a recursion with an irreducible factor of desired degree  $p$  in  $\chi_f(t)$ . Then, we have a factorization

$$\chi_f = \phi_p \phi_r,$$

where  $\phi_p$  is a primitive polynomial of degree  $p$  and  $\phi_r$  is a polynomial of degree  $r \leq wN - p$ . These are coprime, since we assume  $p > r$ . By putting  $V_p := \text{Ker} \phi_p(f)$  and  $V_r := \text{Ker} \phi_r(f)$ , we have a decomposition into  $f$ -invariant subspaces

$$S = V_p \oplus V_r,$$

For any element  $s \in S$ , we denote  $s = s_p + s_r$  for the corresponding decomposition.

The period length of the state transition is the least common multiple of that started from  $s_p$  and that started from  $s_r$ . Hence, if  $s_p \neq 0$ , then the period is a nonzero multiple of  $2^p - 1$ . We checked the following.

**Proposition 1.** *The period of SFMT19937 as 128-bit integer generator is a nonzero multiple of  $2^{19937} - 1$ , if the 32 MSBs of  $\mathbf{w}_0$  is set to the value 6d736d6d in hexadecimal form.*

This value of  $\mathbf{w}_0$  assures that  $s_p \neq 0$ , see [13] for a way to find such a value.

*Remark 1.* The number of non-zero terms in  $\chi_f(t)$  is an index measuring the amount of bit-mixing. In the case of SFMT19937, the number of nonzero terms is 6711, which is much larger than 135 of MT, but smaller than 8585 of WELL19937c [12].

### 3.2 Computation of the dimension of equidistribution

We briefly recall the definition of dimension of equidistribution (cf. [3]).

**Definition 1.** *A periodic sequence with period  $P$*

$$\chi := \mathbf{x}_0, \mathbf{x}_1, \dots, \mathbf{x}_{P-1}, \mathbf{x}_P = \mathbf{x}_0, \dots$$

*of  $v$ -bit integers is said to be  $k$ -dimensionally equidistributed if any  $kv$ -bit pattern occurs equally often as a  $k$ -tuple*

$$(\mathbf{x}_i, \mathbf{x}_{i+1}, \dots, \mathbf{x}_{i+k-1})$$

*for a period  $i = 0, \dots, P - 1$ . We allow an exception for the all-zero pattern, which may occur once less often. (This last loosening of the condition is technically necessary, because the zero state does not occur in an  $\mathbb{F}_2$ -linear generator). The largest value of such  $k$  is called the dimension of equidistribution (DE).*

We want to generalise this definition slightly. We define the  $k$ -window set of the periodic sequence  $\chi$  as

$$W_k(\chi) := \{(\mathbf{x}_i, \mathbf{x}_{i+1}, \dots, \mathbf{x}_{i+k-1}) | i = 0, 1, \dots, P - 1\},$$

which is considered as a *multi-set*, namely, the multiplicity of each element is considered.

For a positive integer  $m$  and a multi-set  $T$ , let us denote by  $m \cdot T$  the multi-set where the multiplicity of each element in  $T$  is multiplied by  $m$ . Then, the above definition of equidistribution is equivalent to

$$W_k(\chi) = (m \cdot \mathbb{F}_2^{vk}) \setminus \{\mathbf{0}\},$$

where  $m$  is the multiplicity of the occurrences, and the operator  $\setminus$  means that the multiplicity of  $\mathbf{0}$  is subtracted by one.

**Definition 2.** *In the above setting, if there exist a positive integer  $m$  and a multi-subset  $D \subset (m \cdot \mathbb{F}_2^{vk})$  such that*

$$W_k(\chi) = (m \cdot \mathbb{F}_2^{vk}) \setminus D,$$

*we say that  $\chi$  is  $k$ -dimensionally equidistributed with defect ratio  $\#(D)/\#(m \cdot \mathbb{F}_2^{vk})$ , where the cardinality is counted with multiplicity.*

Thus, in Definition 1, the defect ratio up to  $1/(P+1)$  is allowed to claim the dimension of equidistribution. If  $P = 2^{19937} - 1$ , then  $1/(P+1) = 2^{-19937}$ . In the following, the dimension of equidistribution allows the defect ratio up to  $2^{-19937}$ .

For a  $w$ -bit integer sequence, its *dimension of equidistribution at  $v$ -bit accuracy*  $k(v)$  is defined as the DE of the  $v$ -bit sequence, obtained by extracting the  $v$  MSBs from each of  $w$ -bit integers. If the defect ratio is  $1/(P+1)$ , then there is an upper bound

$$k(v) \leq \lfloor \log_2(P+1)/v \rfloor.$$

The gap between the realized  $k(v)$  and the upper bound is called the dimension defect at  $v$  of the sequence, and denoted by

$$d(v) := \lfloor \log_2(P+1)/v \rfloor - k(v).$$

The summation of all the dimension defects at  $1 \leq v \leq 32$  is called the total dimension defect, denoted by  $\Delta$ .

There is a difficulty in computing  $k(v)$  when a 128-bit integer generator is used as a 32-bit (or 64-bit) integer generator. SFMT generates a sequence  $\mathbf{x}_0, \mathbf{x}_1, \mathbf{x}_2, \dots$  of 128-bit integers. Then, they are converted to a sequence of 32-bit integers  $\mathbf{x}_0[0], \mathbf{x}_0[1], \mathbf{x}_0[2], \mathbf{x}_0[3], \mathbf{x}_1[0], \mathbf{x}_1[1], \dots$ , where  $\mathbf{x}[0]$  is the 32 LSBs of  $\mathbf{x}$ ,  $\mathbf{x}[1]$  is the 33rd–64th bits,  $\mathbf{x}[2]$  is the 65rd–96th bits, and  $\mathbf{x}[3]$  is the 32 MSBs. This is the so-called little-endian system (see §8.2 for an implementation in a big-endian system).

Then, we need to modify the model automaton as follows. The state space is  $S' := S \times \{0, 1, 2, 3\}$ , the state transition function  $f' : S' \rightarrow S'$  is

$$f'(s, i) := \begin{cases} (s, i+1) & (\text{if } i < 3), \\ (f(s), 0) & (\text{if } i = 3) \end{cases}$$

and the output function is

$$o' : S' \rightarrow \mathbb{F}_2^{32}, ((\mathbf{w}_0, \dots, \mathbf{w}_{N-1}), i) \mapsto \mathbf{w}_0[i].$$

We fix  $1 \leq v \leq w$ , and let  $o_k(s, i)$  be the  $k$ -tuple of the  $v$  MSBs of the consecutive  $k$ -outputs from the state  $(s, i)$ .

**Proposition 2.** *Assume that  $f$  is bijective. Let  $k' = k'(v)$  denote the maximum  $k$  such that*

$$o_k(-, i) : V_p \subset S \rightarrow \mathbb{F}_2^{kv}, \quad s \mapsto o_k(s, i) \quad (3)$$

is surjective for all  $i = 0, 1, 2, 3$ . Take the initial state  $s$  satisfying  $s_p \neq 0$ . Then, the 32-bit output sequence is at least  $k'(v)$ -dimensionally equidistributed with  $v$ -bit accuracy with defect ratio  $2^{-p}$ .

Moreover, if  $4 < k'(v) + 1$ , then for any initial state with  $s = s_p \neq 0$  (hence  $s_r = 0$ ), the dimension of equidistribution with defect ratio  $2^{-p}$  is exactly  $k'(v)$ .

*Proof.* Take  $s \in S$  with  $s_p \neq 0$ . Then, the orbit of  $s$  by  $f$  has the form of  $(V_p - \{0\}) \times U \subset V_p \times V_r$ , since  $p > r$  and  $2^p - 1$  is a prime. The surjectivity of the linear mapping  $o_{k'}(-, i)$  implies that the image of

$$o_{k'+1}(-, i) : V_p \times U \rightarrow \mathbb{F}_2^{kv}$$

is  $m \cdot \mathbb{F}_2^{kv}$  as a multi-set for some  $m$ . The defect comes from  $0 \in V_p$ , whose ratio in  $V_p$  is  $2^{-p}$ . Then the first statement follows, since  $W_{k'}(\chi)$  is the union of the images  $o_{k'}(-, i)((V_p - \{0\}) \times U)$  for  $i = 0, 1, 2, 3$ .

For the latter half, we define  $L_i$  as the multiset of the image of  $o_{k'+1}(-, i) : V_p \rightarrow \mathbb{F}_2^{(k'+1)v}$ . By the choice of  $s_r = 0$ , we have  $U = \{0\}$ , and the union of  $(L_i - \{0\})$  ( $i = 0, 1, 2, 3$ ) as a multi-set is  $W_{k'+1}(\chi)$ . If the sequence is  $(k' + 1)$ -dimensionally equidistributed, then the multiplicity of each element in  $W_{k'+1}(\chi)$  is at most  $2^p \times 4/2^{(k'+1)v}$ .

On the other hand, the multiplicity of an element in  $L_i$  is equal to the cardinality of the kernel of  $o_{k'+1}(-, i)$ . Let  $d_i$  be its dimension. Then by the dimension theorem, we have  $d_i \geq p - (k' + 1)v$ , and the equality holds if and only if  $o_{k'+1}(-, i)$  is surjective. Thus, if there is a nonzero element  $x \in \cap_{i=0}^3 L_i$ , then its multiplicity in  $W_{k'+1}(\chi)$  is no less than  $4 \times 2^{p-(k'+1)v}$ , and since one of  $o_{k'+1}(-, i)$  is not surjective by the definition of  $k'$ , its multiplicity actually exceeds  $4 \times 2^{p-(k'+1)v}$ , which implies that the sequence is not  $(k' + 1)$ -dimensionally equidistributed, and the proposition follows. Since the codimension of  $L_i$  is at most  $v$ , that of  $\cap_{i=0}^3 L_i$  is at most  $4v$ . The assumed inequality on  $k'$  implies the existence of nonzero element in the intersection.

The dimension of equidistribution  $k(v)$  depends on the choice of the initial state  $s$ . The above proposition implies that  $k'(v)$  coincides with  $k(v)$  for the worst choice of  $s$  under the condition  $s_p \neq 0$ . Thus, we adopt the following definition.

**Definition 3.** Let  $k$  be the maximum such that (3) is satisfied. We call this the dimension of equidistribution of  $v$ -bit accuracy, and denote it simply by  $k(v)$ . We have an upper bound  $k(v) \leq \lfloor p/v \rfloor$ .

We define the dimension defect at  $v$  by

$$d(v) := \lfloor p/v \rfloor - k(v) \text{ and } \Delta := \sum_{v=1}^w d(v).$$

We may compute  $k'(v)$  by standard linear algebra. We used a more efficient algorithm based on a weighted norm, generalising [3]. This will be written somewhere else, because of lack of space.

## 4 Comparison of speed

We compared two algorithms: MT19937 and SFMT19937, with implementations using and without using SIMD instructions.

We measured the speeds for four different CPUs: Pentium M 1.4GHz, Pentium IV 3GHz, AMD Athlon 64 3800+, and PowerPC G4 1.33GHz. In returning the random values, we used two different methods. One is sequential generation, where one 32-bit random integer is returned for one call. The other is block generation, where an array of random integers is generated for one call (cf. [5]). For detail, see §7 below.

We measured the consumed CPU time in second, for  $10^8$  generations of 32-bit integers. More precisely, in case of the block generation, we generate  $10^5$  of 32-bit random integers by one call, and it is iterated for  $10^3$  times. For sequential generation, the same  $10^8$  32-bit integers are generated, one per a call. We used the inline declaration `inline` to avoid the function call, and unsigned 32-bit, 64-bit integer types `uint32_t`, `uint64_t` defined in INTERNATIONAL STANDARD ISO/IEC 9899 : 1999(E) Programming Language-C, Second Edition (which we shall refer to as C99 in the rest of this article). Implementations without SIMD are written in C99, whereas those with SIMD use some standard SIMD extension of C99 supported by the compilers `icl` (Intel C compiler) and `gcc`.

Table 1 summarises the speed comparisons. The first four lines list the CPU time (in second) needed to generate  $10^8$  32-bit integers, for a Pentium-M CPU with the Intel C/C++ compiler. The first line lists the seconds for the block-generation scheme. The second line shows the ratio of CPU time to that of SFMT(SIMD). Thus, SFMT coded in SIMD is 2.10 times faster than MT coded in SIMD, and 3.77 times faster than MT without SIMD. The third line lists the seconds for the sequential generation scheme. The fourth line lists the ratio, with the basis taken at SFMT(SIMD) block-generation (not sequential). Thus, the block-generation of SFMT(SIMD) is 2.00 times faster than the sequential-generation of SFMT(SIMD).

Roughly speaking, in the block generation, SFMT(SIMD) is twice as fast as MT(SIMD), and four times faster than MT without using SIMD. Even in the sequential generation case, SFMT(SIMD) is still considerably faster than MT(SIMD).

Table 2 lists the CPU time for generating  $10^8$  32-bit integers, for four PRNGs from the GNU Scientific Library and two recent generators. They are re-coded with inline specification. Generators examined were: a multiple recursive generator `mrng` [6], linear congruential generators `rand48` and `rand`, a lagged fibonacci generator `random256g2`, a WELL generator `well`

|            | seq    | 2.508 | 1.132  | 0.378 | 1.072       | 1.762 | 1.153 |

**Table 2.** The CPU time (sec.) for  $10^8$  generations of 32-bit integers, by six other PRNGs.

(WELL19937c in [12]), and a XORSHIFT generator `xor3` [11] [7]. The table shows that SFMT(SIMD) is faster than these PRNGs, except for the lagged-fibonacci generator `random256g2` with a Pentium IV (but this method is known to have poor randomness, cf. [10]), and `xor3` with a Pentium-M.

## 5 Dimension of equidistribution

The total dimension defect  $\Delta'$  of SFMT19937 as a 32-bit integer generator is 4188, which is smaller than the total dimension defect 6750 of MT19937. Table 3 lists the dimension defects  $d(v)$  of SFMT19937 (as a 32-bit integer

generator) and the dimension defects MT19937 for  $v = 1, 2, \dots, 32$ . SFMT has smaller values of the defect  $d(v)$  at 26 values of  $v$ . The converse holds for 6 values of  $v$ , but the difference is small.

| $v$    | MT  | SFMT | $v$     | MT  | SFMT | $v$     | MT  | SFMT | $v$     | MT  | SFMT |
|--------|-----|------|---------|-----|------|---------|-----|------|---------|-----|------|
| $d(1)$ | 0   | 0    | $d(9)$  | 346 | 1    | $d(17)$ | 549 | 543  | $d(25)$ | 174 | 173  |
| $d(2)$ | 0   | *2   | $d(10)$ | 124 | 0    | $d(18)$ | 484 | 478  | $d(26)$ | 143 | 142  |
| $d(3)$ | 405 | 1    | $d(11)$ | 564 | 0    | $d(19)$ | 426 | 425  | $d(27)$ | 115 | 114  |
| $d(4)$ | 0   | *2   | $d(12)$ | 415 | 117  | $d(20)$ | 373 | 372  | $d(28)$ | 89  | 88   |
| $d(5)$ | 249 | 2    | $d(13)$ | 287 | 285  | $d(21)$ | 326 | 325  | $d(29)$ | 64  | 63   |
| $d(6)$ | 207 | 0    | $d(14)$ | 178 | 176  | $d(22)$ | 283 | 282  | $d(30)$ | 41  | 40   |
| $d(7)$ | 355 | 1    | $d(15)$ | 83  | *85  | $d(23)$ | 243 | 242  | $d(31)$ | 20  | 19   |
| $d(8)$ | 0   | *1   | $d(16)$ | 0   | *2   | $d(24)$ | 207 | 206  | $d(32)$ | 0   | *1   |

**Table 3.** Dimension defects  $d(v)$  of MT19937 and SFMT19937 as a 32-bit integer generator. The mark \* means that MT has a smaller defect than SFMT at that accuracy.

We also computed the dimension defects of SFMT19937 as a 64-bit (128-bit) integer generator, and the total dimension defect  $\Delta'$  is 14089 (28676, respectively). In some applications, the distribution of LSBs is important. To check them, we inverted the order of the bits (i.e. the  $i$ -th bit is exchanged with the  $(w - i)$ -th bit) in each integer, and computed the total dimension defect. It is 10328 (21337, 34577, respectively) as a 32-bit (64-bit, 128-bit, respectively) integer generator. Throughout the experiments,  $d'(v)$  is very small for  $v \leq 10$ . We consider that these values are satisfactorily small, since they are comparable with MT for which no statistical problem related to the dimension defect has been reported, as far as we know.

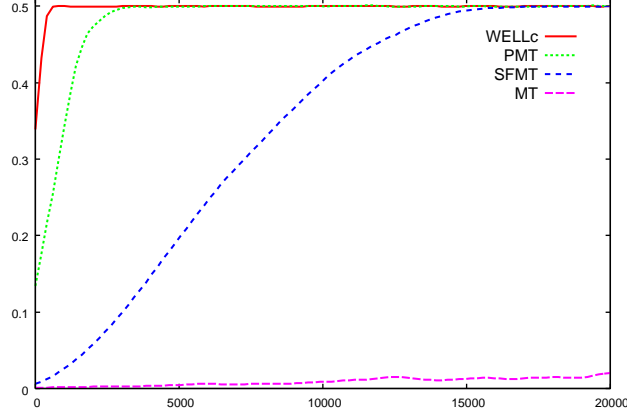

## 6 Recovery from 0-excess states

LFSR with a sparse feedback function  $g$  has the following phenomenon: if the bits in the state space contain too many 0's and few 1's (called a 0-excess state), then this tendency continues for considerable generations, since only a small part is changed in the state array at one generation, and the change is not well-reflected to the next generation because of the sparseness.

We measure the recovery time from 0-excess states, by the method introduced in [12], as follows.

1. Choose an initial state with only one bit being 1.
2. Generate  $k$  pseudorandom numbers, and discard them.
3. Compute the ratio of 1's among the next 32000 bits of outputs (i.e., in the next 1000 pseudorandom 32-bit integers).
4. Let  $\gamma_k$  be the average of the ratio over all such initial states.

We draw graphs of these ratio  $\gamma_k$  ( $1 \leq k \leq 20000$ ) in Figure 2 for the following generators: (1) WELL19937c, (2) PMT19937 [13], (3) SFMT19937, and (4) MT19937. Because of its dense feedback, WELL19937c shows the fastest

**Fig. 2.**  $\gamma_k$  ( $k = 0, \dots, 20000$ ): Starting from extreme 0-excess states, discard the first  $k$  outputs and then measure the ratio  $\gamma_k$  of 1's in the next 1000 outputs. In the order of the recovery speed: (1) WELL19937c, (2) PMT19937, (3) SFMT19937, and (4) MT19937.

recovery among the compared. SFMT is better than MT, since its recursion refers to the previously-computed words (i.e.,  $W[N-1]$  and  $W[N-2]$ ) that acquire new 1s, while MT refers only to the words generated long before (i.e.,  $W[M]$  and  $W[0]$ ). PMT19937 shows faster recovery than SFMT19937, since PMT19937 has two feedback loops (hence the name of Pulmonary Mersenne Twister).

The speed of recovery from 0-excess states is a trade-off with the speed of generation. Such 0-excess states will not happen practically, since the probability that 19937 random bits have less than  $19937 \times 0.4$  of 1's is about  $5.7 \times 10^{-177}$ . The only plausible case is that a poor initialization scheme gives a 0-excess initial state. In a typical simulation, the number of initializations is far smaller than the number of generations, therefore we may spend more CPU time in the initialization than the generation. Once we avoid the 0-excess initial state by a well-designed initialization, then the recovery speed does not matter, in a practical sense. Consequently, the slower recovery of SFMT compared to WELL is not an issue, under the assumption that a good initialization scheme is provided.

## 7 Block-generation

In the block-generation scheme, the user of the PRNG specifies an array of  $w$ -bit integers of the length  $L$ , where  $w = 32, 64$  or  $128$  and  $L$  is specified by the user. In the case of SFMT19937,  $wL$  should be a multiple of 128 and no less than  $N \times 128$ , since the array needs to accommodate the state space (note that  $N = 156$ ). By calling the block generation function with the pointer to this array,  $w$ , and  $L$ , the routine fills up the array with pseudorandom integers, as follows. SFMT19937 keeps the state space  $S$  in an internal array of 128-bit integers of length 156. We concatenate this state array with the user-specified array, using the indexing technique. Then, the routine generates 128-bit integers in the user-specified array by recursion (2), as described in Figure 3, until it fills up the array. The last 156 128-bit integers are copied back to the internal array of SFMT19937. This makes the generation much faster than sequential generation (i.e., one generation per one call) as shown in Table 1.

**Fig. 3.** Block-generation scheme

## 8 Concluding remarks

We proposed SFMT pseudorandom number generator, which is a very fast generator with satisfactorily high dimensional equidistribution property.

### 8.1 Trade-off between speed and quality

It is difficult to measure the generation speed of a PRNG in a fair way, since it depends heavily on the circumstance. The WELL [12] generators have the best possible dimensions of equidistribution (i.e.  $\Delta = 0$ ) for various periods ( $2^{1024}-1$  to  $2^{19937}-1$ ). If we use the function call to PRNG for each generation, then a large part of the CPU time is consumed for handling the function call, and in the experiments in [12] or [11], WELL is not much slower than MT. On the other hand, if we avoid the function call, WELL is much slower than MT as seen in Table 1.

Since  $\Delta = 0$ , WELL has a better quality than MT or SFMT in a theoretical sense. However, one may argue whether this difference is observable or not. In the case of an  $\mathbb{F}_2$ -linear generator, the dimension of equidistribution  $k(v)$  of  $v$ -bit accuracy means that there is no constant linear relation among the  $kv$  bits, but there exists a linear relation among the  $(k+1)v$  bits, where  $kv$  bits ( $(k+1)v$  bits) are taken from all the consecutive  $k$  integers ( $k+1$  integers, respectively) by extracting the  $v$  MSBs from each. However, the existence of a linear relation does not necessarily mean the existence of some observable bias. According to [9], it requires  $10^{28}$  samples to detect an  $\mathbb{F}_2$ -linear relation with 15 (or more) terms among 521 bits, by a standard statistical test. If the number of terms is increased, the necessary sample size is increased exponentially. Thus, it seems that  $k(v)$  of SFMT19937 is sufficiently large, far beyond the level of the observable bias. On the other hand, the speed of the generator is observable. Thus, SFMT focuses more on the speed, for applications that require fast generations.

### 8.2 Trade-off between speed and portability

There is a trade-off between the speed and portability. We prepare (1) a standard C code of SFMT, which uses functions specified in C99 only, (2) an optimized C code for Intel Pentium SSE2, and (3) an optimized C code for PowerPC AltiVec. The optimized codes require icl (Intel C Compiler) or gcc compiler with suitable options. We will put the newest version of the codes in a link from the homepage of [8], together with some notes on compiling with SIMD.

There is a problem of the endian when 128-bit integers are converted into 32-bit integers. When a 128-bit integer is stored as an array of 32-bit integers with length 4, in a little endian system such as Pentium, the 32 LSBs of the 128-bit integer come first. On the other hand, in a big endian system such as PowerPC, the 32 MSBs come first. The explanation above is based on the former. To assure the exactly same outputs for both endian systems as 32-bit integer generators, in the SIMD implementation for PowerPC, the recursion (2) is considered as a recursion on quadruples of 32-bit integers, rather than 128-bit integers, so that the content of the state array coincides both for little and big endian systems, as an array of 32-bit integers (not as 128-bit integers).

Then, shift operations on 128-bit integers in PowerPC differs from those of Pentium. Fortunately, PowerPC supports arbitrary permutations of 16 blocks of 8-bit integers in a 128-bit register, which emulates the Pentium's shift by a multiple of 8.
